

DD4hep

A Detector Description Toolkit
for High Energy Physics
Experiments

M.Frank
CERN, 1211 Geneva 23, Switzerland

Abstract

The detector description is an essential component that is used to analyze data resulting from particle collisions in high energy physics experiments. We will present a generic detector description toolkit and describe the guiding requirements and the architectural design for such a toolkit, as well as the main implementation choices. The design is strongly driven by easy of use; developers of detector descriptions and applications using them should provide minimal information and minimal specific code to achieve the desired result. The toolkit will be built reusing already existing components from the ROOT geometry package and provides missing functional elements and interfaces to offer a complete and coherent detector description solution. A natural integration to Geant4, the detector simulation program used in high energy physics, is provided.

1 Introduction and General Overview

The development of a coherent set of software tools for the description of High Energy Physics detectors from a single source of information has been on the agenda of many experiments for decades. Providing appropriate and consistent detector views to simulation, reconstruction and analysis applications from a single information source is crucial for the success of the experiments. Detector description in general includes not only the geometry and the materials used in the apparatus, but all parameters describing e.g. the detection techniques, constants required by alignment and calibration, description of the readout structures, conditions data, etc.

The design of the DD4hep toolkit[1] is shaped on the experience of detector description systems, which were implemented for the LHC experiments, in particular the LHCb experiment [2, 3], as well as the lessons learnt from other implementations of geometry description tools developed for the Linear Collider community [4, 5]. Designing a coherent set of tools, with most of the basic components already existing in one form or another, is an opportunity for getting the best of all existing solutions. DD4hep aims to widely reuse used existing software components, in particular the ROOT geometry package [6], part of the ROOT project[7], a tool for building, browsing, navigating and visualizing detector geometries. The code is designed to optimize particle transport through complex structures and works standalone with respect to any Monte-Carlo simulation engine. The ROOT geometry package provides sophisticated 3D visualization functionality, which is ideal for building detector and event displays. The second component is the Geant4 simulation toolkit [8], which is used to simulate the detector response from particle collisions in complex designs. In DD4hep the geometrical representation provided by ROOT is the main source of information. In addition DD4hep provides the automatic conversions to other geometrical representations, such as Geant4, and the convenient usage of these components without the reinvention of the existing functionality.

In Section 1.1 the scope and the high-level requirements of the DD4hep toolkit are elaborated (in the following also called "the toolkit"). This is basically the high level vision of the provided functionality to the experimental communities. In Section 1.2 the high-level or architectural design of the toolkit is presented, and in subsequent subsections design aspects of the various functional components and their interfaces will be introduced.

1.1 Project Scope and Requirements

The detector description should fully describe and qualify the detection apparatus and must expose access to all information required to interpret event data recorded from particle collisions. Experience from the LHC experiments has shown that a generalized view, not limited only to geometry, is very beneficial in order to obtain a coherent set of tools for the interpretation of collision data. This is particularly important in later stages of the experiment's life cycle, when a valid set of detector data must be used to analyze real or simulated detector response from particle collisions. An example would be an alignment application, where time dependent precise detector positions are matched with the detector geometry.

The following main requirements influenced the design of the toolkit:

- **Full Detector Description.** The toolkit should be able to manage the data describing the detector geometry, the materials used when building the structures, visualization attributes, detector readout information, alignment, calibration and environmental parameters - all that is necessary to interpret event data recorded from particle collisions.
- **The Full Experiment Life Cycle** should be supported. The toolkit should support the development of the detector concepts, detector optimizations, construction and later operation of the detector. The transition from one phase to the next should be simple and not require new developments. The initial phases are characterized by very *ideal* detector descriptions, i.e. only very few parameters are sufficient to describe new detector designs. Once operational, the detector will be different from the ideal detector, and each part of the detector will have to have its own specific parameters and conditions, which are exposed by the toolkit.

- **One single source of detector information** must be sufficient to perform all data processing applications such as simulation, reconstruction, online trigger and data analysis. This ensures that all applications see a coherent description. In the past attempts by experiments to re-synchronize parallel detector descriptions were always problematic. Consequently, the detector description is the union of the information needed by all applications, though the level of detail may be selectable.
- **Ease of Use** influenced both the design and the implementation. The definition of subdetectors, their geometrical description and the access to conditions and alignment data should follow a minimalistic, simple and intuitive interface. Hence, the of the developer using the toolkit is focused on specifics of the detector design and not on technicalities handled transparently by the

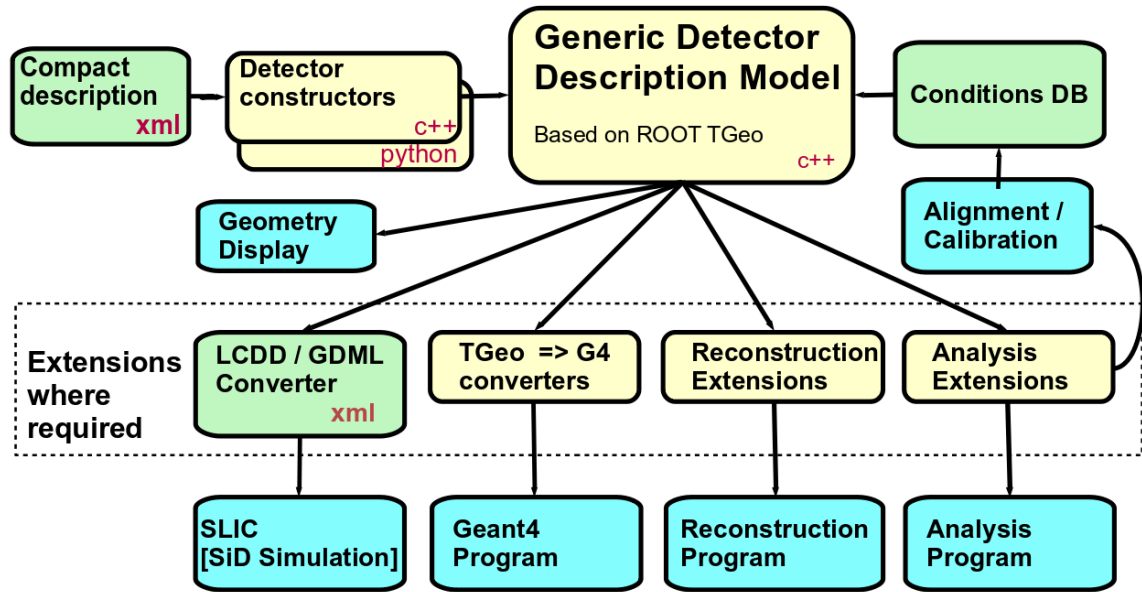

Figure 1: The components of the DD4hep detector geometry toolkit.

1.2 Toolkit Design

Figure 1 shows the architecture of the main components of the toolkit and their interfaces to the end-user applications, namely the simulation, reconstruction, alignment and visualization. The central element of the toolkit is the so-called generic detector description model. This is an in-memory model, i.e., a set of C++ objects holding the data describing the geometry and other information of the detector. The rest of the toolkit consists of tools and interfaces to input or output information from this generic detector model. The model and its components will be described in subsequent sections.

1.2.1 The Compact Detector Description

Inspired from the work of the linear collider detector simulation [9, 10], the compact detector description is used to define an ideal detector as typically used during the conceptual design phase of an experiment. The compact description in its minimalistic form is probably not going to be adequate later in the detector life cycle and is likely to be replaced or refined when a more realistic detector with deviations from the ideal would be needed by the experiment.

In the compact description the detector is parametrized in minimalistic terms with user provided parameters in XML. XML is an open format, the DD4hep parsers do not validate against a fix schema and hence allow to easily introduce new elements and attributes to describe detectors. This feature minimizes the burden on the end-user while still supporting flexibility. Such a compact detector

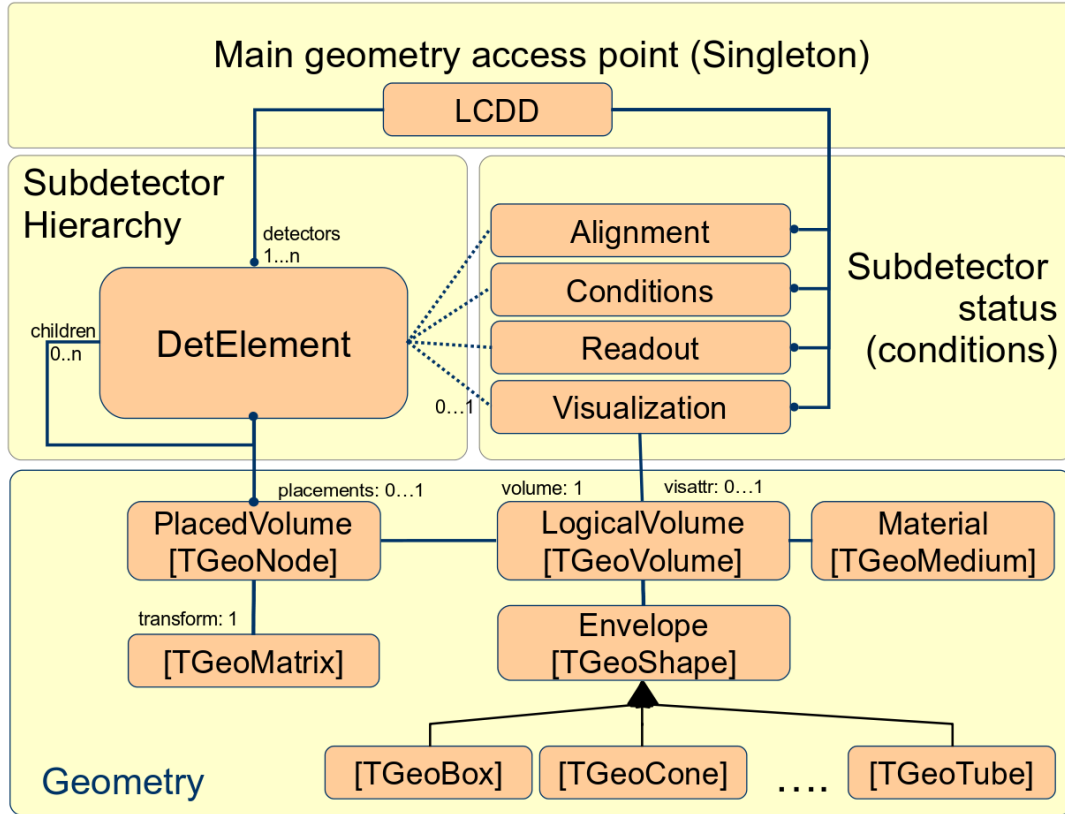

Figure 2: Class diagram with the main classes and their relations for the Generic Detector Description Model. The implementing ROOT classes are shown in brackets.

descriptions cannot be interpreted in a general manner, therefore so called *Detector Constructors* are needed.

1.2.2 Detector Constructors

Detector Constructors are relatively small code fragments that get as input an XML element from the compact description that represents a single detector instance. The code interprets the data and expands its geometry model in memory using the elements from the generic detector description model described in section 1.3. The toolkit invokes these code fragments in a data driven way using naming conventions during the initialization phase of the application. Users focus on one single detector type at the time, but the toolkit supports them to still construct complex and large detector setups. Two implementations are currently supported: One is based on C++, which performs better and is able to detect errors at compiler time, but the code is slightly more technical. The other is based on Python fragments, the code is more readable and compact but errors are only detected at execution time. The compact description together with the detector constructors are sufficient to build the detector model and to visualize it. If during the lifetime of the experiment the detector model changes, the corresponding constructors will need to be adapted accordingly. DD4hep provides already a palette of basic pre-implemented geometrical detector concepts to design experiments. In view of usage of DD4hep as a detector description toolkit, this library may in the future also adopt generic designs of detector components created by end users e.g. during the design phase of future experiments.

1.3 Generic Detector Description Model

This is the heart of the DD4hep detector description toolkit. Its purpose is to build in memory a model of the detector including its geometrical aspects as well as structural and functional aspects.

The design reuses the elements from the ROOT geometry package and extends them in case required functionality is not available. Figure 2 illustrates the main players and their relationships. Any detector is modeled as a tree of *Detector Elements*, the entity central to this design, which is represented in the implementation by the *DetElement* class [3]. It offers all applications a natural entry point to any detector part of the experiment and represents a complete sub-detector (e.g. TPC), a part of a sub-detector (e.g. TPC-Endcap), a detector module or any other convenient detector device. The main purpose is to give access to the data associated to the detector device. For example, if the user writes some TPC reconstruction code, accessing the TPC detector element from this code will provide access the all TPC geometrical dimensions, the alignment and calibration constants and other slow varying conditions such as the gas pressure, end-plate temperatures etc. The *Detector Element* acts as a data concentrator. Applications may access the full experiment geometry and all connected data through a singleton object called *LCDD*, which provides management, bookkeeping and ownership to the model instances.

The geometry is implemented using the ROOT geometry classes, which are used directly without unnecessary interfaces to isolate the end-user from the actual ROOT based implementation. There is one exception: The constructors are wrapped to facilitate a very compact and readable notation to end-users building custom *Detector Constructors*.

1.3.1 Detector Element Tree versus the Geometry Hierarchy

The geometry part of the detector description is delegated to the ROOT classes. *Logical Volumes* are the basic objects used in building the geometrical hierarchy. A *Logical Volume* is a shape with its dimensions and consist of a given material. They represent unpositioned objects which store all information about the placement of possibly embedded volumes. The same volume can be replicated several times in the geometry. The *Logical Volume* also represents a system of reference with respect to its containing volumes. The reuse of instances of *Logical Volumes* for different placements optimizes the memory consumption and detailed geometries for complex setups consisting of millions of volumes may be realized with reasonable amount of memory. The difficulty is to identify a given positioned volume in space and e.g. applying misalignment to one of these volumes. The relationship between the Detector Element and the placements is not defined by a single reference to the placement, but the full path from the top of the detector geometry model to resolve existing ambiguities due to the reuse of *Logical Volumes*. Hence, individual volumes must be identified by their full path from mother to daughter starting from the top-level volume.

The tree structure of Detector Elements is a parallel structure to the geometrical hierarchy. This structure will probably not be as deep as the geometrical one since there would not need to associate detector information at very fine-grain level - it is unlikely that every little metallic screw needs associated detector information such as alignment, conditions, etc. Though this screw and many other replicas must be described in the geometry description since it may be important e.g. for its material contribution in the simulation application. Thus, the tree of Detector Elements is fully degenerate and each detector element object will be placed only once in the detector element tree as illustrated for a hypothetical TPC detector in Figure 3.

1.3.2 Extensions and Views

As depicted in Figure 1 the reconstruction application will require special functionality extending the basics offered by the common detector element. This functionality may be implemented by a set of specialized classes that will extend the detector element. These extensions will be in charge of providing specific answers to the questions formulated by the reconstruction algorithms such as pattern recognition, tracking, vertexing, particle identification, etc. One example could be to transform a calorimeter cell identifier into a 3D space position in the global coordinate system. A generic detector description toolkit would be unable to answer this concrete question, however it provides a convenient environment for the developer to slot-in code fragments, which implement the additional functionality using parameters stored in the XML compact description.

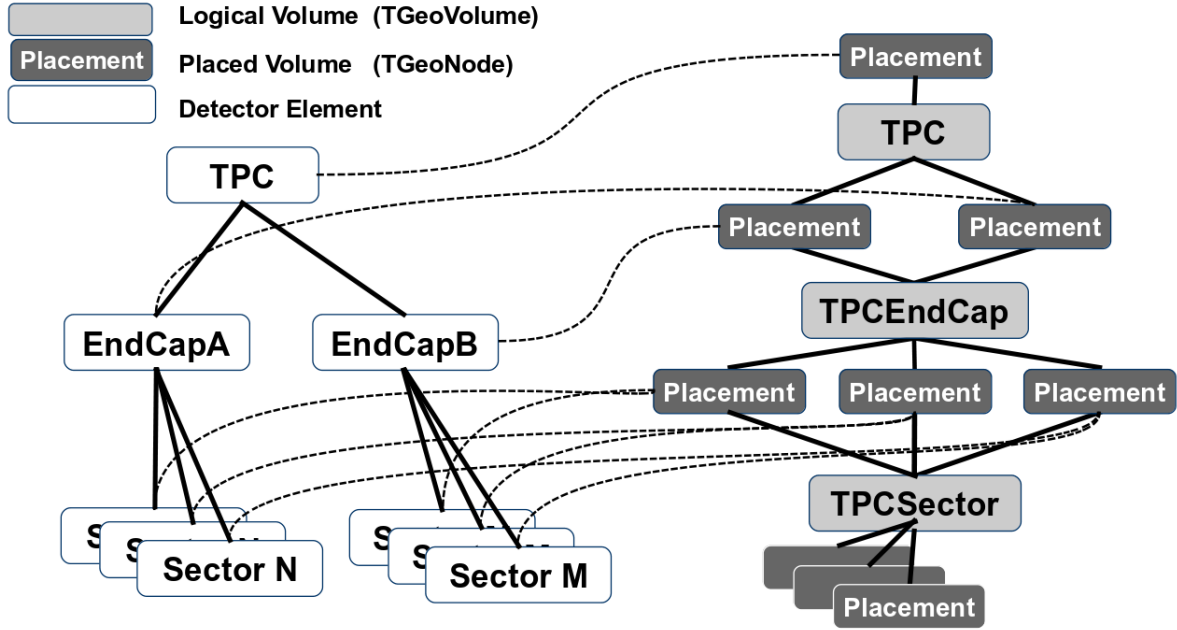

Figure 3: The object diagram of a hypothetical TPC detector showing in parallel the *Detector Element* and the *Geon*

Figure 4: Extensions may be attached to common Detector Elements which extend the functionality of the common *DetElement* class and support e.g. caching of precomputed values.

Depending on the functionality these specialized component must be able to either store additional data, expose additional behavior or both. Additional behavior may easily be added overloading the *DetElement* class using its internal data. The internal data is public and addressed by reference, hence any number of views extending the *DetElement* behavior may be constructed with very small overhead. Additional data may be added by any user at any time to any instance of the *DetElement* class using a simple aggregation mechanism shown in Figure 4. Data extensions must differ by their type. The freedom to attach virtually any data item allows for optimized attachments depending on the application type, such as special attachments for reconstruction, simulation, tracking, etc. This design allows to build views addressing the following use-cases:

- **Convenience Views** provide higher level abstractions and internally group complex calculations. Such views simplify the life of the end-users.
- **Optimization Views** allows end-users extend the data of the common detector detector element and store precomputed results, which would be expensive to obtain repeatedly.
- **Compatibility Views** help to ensure smooth periods of software redesign. During the life-time of the experiment often various software constructs are for functional reasons re-designed and re-engineered. Compatibility Views either adapt new data designs to existing application code or expose new behavior based on existing data.

1.4 Simulation Support

Detector-simulation depends strongly on the use of an underlying simulation toolkit, the most prominent candidate nowadays being Geant4 [8]. DD4hep supports simulation activities with Geant4 providing an automatic translation mechanism between geometry representations. The simulation response in the active elements of the detector is not implemented by the toolkit, since it is strongly influenced by the technical choices and precise simulations depends on the very specific detection techniques. In Geant4 this response is computed in software constructs called *Sensitive Detectors*.

Ideally DD4hep aims to provide a generic simulation application. Similar to the palette of pre-implemented geometrical detector concepts to design experiments, it provides a palette of *Sensitive Detectors* to simulate the detector response in form of a component library. Detector designers may base the simulation of a planned experiment on these predefined components for initial design and optimization studies. In a similar way easy access and configuration of other user actions of Geant4 is provided.

1.5 Detector Alignment Support

The support for alignment operations is crucial to the usefulness of the toolkit. In the linear collider community this support is basically missing in all the currently used geometry description systems. The possibility to apply into the detector description alignment *deltas* (differences with respect the ideal or measured position) and read them from an external source is mandatory to exploit the toolkit. A typical alignment application would consist of calculating a new set of *deltas* from a given starting point, which could then be loaded and applied again in order to validate the alignment by recalculating some alignment residuals. The ROOT geometry package supports to apply an [mis]-alignment to *touchable* objects in the geometry. *Touchable* objects are identified by the path of positioned volumes starting with the top node (e.g. path= $/TOP/A_1/B_4/C_3$). Contrary to ordinary multiple placements of *Logical Volumes*, *touchable* objects are degenerate and only valid for one single volume [6]. To simplify the usage for the end user, the identification of a positioned volume will be connected to the Detector Element, where only the relative path with respect to the Detector Element will have to be specified rather the full path from the top volume. The *delta*-values will have to be read from various data sources. The initial implementation will be based on simple XML files, later a connection to other sources such as the detector conditions database is envisaged.

2 User Manual

This chapter describes how supply a physics application developed with all the information related to the detector which is necessary to process data from particle collisions and to qualify the detecting apparatus in order to interpret these event data.

The clients of the detector description are the algorithms residing in the event processing framework that need this information in order to perform their job (reconstruction, simulation, etc.). The detector description provided by DD4hep is a framework for developers to provide the specific detector information to algorithms.

In the following sections an overview is given over the various independent elements of DD4hep followed by the discussion of an example which leads to the description of a detector when combining these elements. This includes a discussion of the features of the DD4hep detector description and of its structure.

2.1 Building DD4hep

The DD4hep source code is freely available. See the [licence conditions](#). Please read the [Release Notes](#) before downloading or using this release.

The DD4hep project consists of several packages. The idea has been to separate the common parts of the detector description toolkit from concrete detector examples.

The package **DDCore** contains the definition of the basic classes of the toolkit: **Handle**, **DetElement**, **Volume**, **PlacedVolume**, **Shapes**, **Material**, etc. Most of these classes are **handles** to ROOT's TGeom classes.

2.1.1 Supported Platforms

Supported platforms for DD4hep are the CERN Linux operating systems:

- **ScientificLinuxCERN6**
- **ScientificLinuxCERN7** - once approved.

Support for any other platform will well be taken into account, but can only be actively supported by users who submit the necessary patches.

2.1.2 Prerequisites

DD4hep depends on a number of external packages. The user will need to install these in his/her system before building and running the examples

- Mandatory are recent **CMake** (version 2.8 or higher) and
- **ROOT** (version 5.34 or higher) installations.
- If the **Xerces – C** is used to parse compact descriptions and installation of Xerces-C will be required.
- To build DDG4 it is useful to have an installation of the Boost header files.
- To build and run the simulation examples **Geant4** will be required.

2.1.3 CMake Build Options for DD4hep

The package provides the basic mechanisms for constructing the *Generic Detector Description Model* in memory from XML compact detector definition files. Two methods are currently supported: one based on the C++Xerces-C parser, and another one based on Python and using the PyROOT bindings to ROOT¹. PyROOT may be enabled using the switch:

```
-DD4HEP_USE_PYROOT:BOOL
```

The XML parsing method is enabled by default using the TiXML parser. Optionally instead of TiXML the Xerces-C parser may be chosen by setting the two configuration options appropriately:

```
-DD4HEP_USE_XERCESC:BOOL
```

```
-DXERCESC_ROOT_DIR=<path to Xerces-C-installation-directory>
```

DDG4 is the package that contains the conversion of DD4hep geometry into Geant4 geometry to be used for simulation. The option `DD4HEP_WITH_GEANT4 : BOOL` controls the building or not of this package that has the dependency to Geant4. The Geant4 installation needs to be located using the variable:

```
-DDD4HEP_WITH_GEANT4=on -D
```

```
-DGeant4_DIR=<path to Geant4Config.cmake>
```

To properly handle component properties using `boost::spirit`, access to the Boost header files must be provided.

```
-DDD4HEP_USE_BOOST=ON
```

```
-DBOOST_INCLUDE_DIR=<path to the boost include directory>
```

Other useful build options:

- build doxygen documentation (after 'install' open `./doc/html/index.html`)

```
-D INSTALL_DOC=on
```
- **note:** you might have to update your environment beforehand to have all needed libraries in the shared lib search path (this will vary with OS, shell, etc.) e.g.

```
. /data/ilcsoft/geant4/9.5/bin/geant4.sh
export CLHEP_BASE_DIR="/data/ilcsoft/HEAD/CLHEP/2.1.0.1"
export CLHEP_INCLUDE_DIR="$CLHEP_BASE_DIR/include"
export PATH="$CLHEP_BASE_DIR/bin:$PATH"
export LD_LIBRARY_PATH="$CLHEP_BASE_DIR/lib:$LD_LIBRARY_PATH"
```

2.1.4 Build From Source

The following steps are necessary to build DD4hep:

- Set the environment, at least ROOT needs to be initialized, e.g.

```
source /data/ilcsoft/root/5.34.03/bin/thisroot.sh
```

(the bare minimum is: `exportROOTSYS =< pathtorootinstallation >`).
- First checkout code from the repository:

```
svn co https://svnsrv.desy.de/public/aidasoft/DD4hep/trunk DD4hep
```
- We refer to the directory **DD4hep** as the source directory. The next step is to create a directory in which to configure and run the build and store the build products. This directory should not be the same as, or inside, the source directory. In this guide, we create this build directory alongside our source directory:

```
mkdir build
cd build
cmake -DCMAKE_INSTALL_PREFIX=<dd4hep-install-pasth> <CMake-options> ../DD4hep
make -j 4
make install
```

The CMake Variable `CMAKE_INSTALL_PREFIX` is used to set the install directory, the directory under which the DD4hep libraries, headers and support files will be installed.

¹I will not continue the support using PyROOT.

If there is a desire that it stays alive someone else should take care – M.Frank

2.1.5 Tutorial

In January 2013 an introductory tutorial was given at CERN to members of the linear collider community. The slides to the tutorial can be found [here](#) . The tutorial is not entirely up to date. Please take the content with a grain of salt.

2.1.6 Doxygen Code Documentation

The DD4hep source code is instrumented with tags understood by doxygen. The generated code documentation can be found [here](#) .

2.1.7 Remarks

The main reference is the doxygen information of DD4hep and the ROOT documentation. Please refer to these sources for a detailed view of the capabilities of each component and/or its handle. For coherence reasons, the description of the interfaces is limited to examples which illustrate the usage of the basic components.

2.1.8 Caveat

The atomic units in of Geant4 are (millimeter, nanosecond and MeV and radians). The atomic units of ROOT-TGeo are (centimeter, seconds, GeV and degrees). Unfortunately the authors could not agree on a common system of units and mixing the two can easily result in a chaos. Users must be aware of this fact.

2.2 DD4hep Handles

Handles are the means of clients accessing DD4hep detector description data. The data itself is not held by the handle itself, the handle only allows the access to the data typically held by a pointer. The template handle class (see for details the header file). allows type safe assignment of other unrelated handles and supports standard data conversions to the underlying object in form of the raw pointer, a reference etc. The template handle class:

```

1 template <typename T> struct Handle {
2     typedef T Implementation;
3     typedef Handle<Implementation> handle_t;
4     T* m_element;
5     Handle() : m_element(0) {
6     Handle(T* e) : m_element(e) {
7     Handle(const Handle<T>& e) : m_element(e.m_element) {
8     template<typename Q> Handle(Q* e)
9     : m_element((T*)e) { verifyObject();
10    template<typename Q> Handle(const Handle<Q>& e)
11    : m_element((T*)e.m_element) { verifyObject();
12    Handle<T>& operator=(const Handle<T>& e) { m_element=e.m_element; return *this;}
13    bool isValid() const { return 0 != m_element;
14    bool operator!() const { return 0 == m_element;
15    void clear() { m_element = 0;
16    T* operator->() const { return m_element;
17    operator T& () const { return *m_element;
18    T& operator*() const { return *m_element;
19    T* ptr() const { return m_element;
20    template <typename Q> Q* _ptr() const { return (Q*)m_element;
21    template <typename Q> Q* data() const { return (Q*)m_element;
22    template <typename Q> Q& object() const { return *(Q*)m_element;
23    const char* name() const;
24 };

```

effectively works like a pointer with additional object validation during assignment and construction. Handles support direct access to the held object: either by using the

`operator->()` (See line 16 above)

or the automatic type conversions:

`operator T& () const` (See line 17-18 above)
`T& operator*() const.`

All entities of the DD4hep detector description are exposed as handles - raw pointers should not occur in the code. The handles to these objects serve two purposes:

- Hold a pointer to the object and extend the functionality of a raw pointer.
- Enable the creation of new objects using specialized constructors within sub-classes. To ensure memory integrity and avoid resource leaks these created objects should always be stored in the detector description data hub *LCDD* described in section 2.5.

2.3 The Data Extension Mechanism

Data extensions are client defined C++ objects aggregated to basic DD4hep objects. The need to introduce such data extensions results from the simple fact that no data structure can be defined without the iterative need in the long term to extend it leading to implementations, which can only satisfy a subset of possible clients. To accomplish for this fact a mechanism was put in place which allows any user to attach any supplementary information provided the information is embedded in a polymorph object with an accessible destructor. There is one limitation though: object extension must differ by their interface type. There may not be two objects attached with the identical interface type. The actual implemented sub-type of the extension is not relevant. Separating the interface type from the implementation type keeps client code still functional even if the implementation of the extension changes or is a plug-able component.

The following code snippet shows the extension interface:

```
1  /// Extend the object with an arbitrary structure accessible by the type
2  template <typename IFACE, typename CONCRETE> IFACE* addExtension(CONCRETE* c);
3  /// Access extension element by the type
4  template <class T> T* extension() const;
```

Assuming a client class of the following structure:

```
1  class ExtensionInterface {
2      virtual ~ExtensionInterface();
3      virtual void foo() = 0;
4  };
5
6  class ExtensionImplementation : public ExtensionInterface {
7      ExtensionImplementation();
8      virtual ~ExtensionImplementation();
9      virtual void foo();
10 };
```

is then attached to an extensible object as follows:

```
1  ExtensionImplementation* ptr = new ExtensionImplementation();
2  ... fill the ExtensionImplementation instance with data ...
3  module.addExtension<ExtensionInterface>(ptr);
```

The data extension may then be retrieved whenever the instance of the extensible object "module" is accessible:

```
1  ExtensionInterface* ptr = module.extension<ExtensionInterface>();
```

The lookup mechanism is rather efficient. Though it is advisable to cache the pointer withing the client code if the usage is very frequent.

There are currently three object types present which support this mechanism:

- the central object of DD4hep, the **LCDD** class discussed in section 2.5.
- the object describing subdetectors or parts thereof, the **DetElement** class discussed in section 2.10. Detector element extensions in addition require the presence of a copy constructor to support e.g. reflection operations. Without a copy mechanism detector element hierarchies could not be cloned.
- the object describing sensitive detectors, the **SensitiveDetector** class discussed in section 2.11.

2.4 XML Tools and Interfaces

Using native tools to interpret XML structures is rather tedious and lengthy. To ease the access to XML data considerable effort was put in place to ease the life of clients as much as possible using predefined constructs to access XML attributes, elements or element collections.

The functionality of the XML tools is perhaps best shown with a small example. Imagine to extract the data from an XML snippet like the following:

```

1 <detector name="Something">
2   <tubs rmin="BP_radius - BP_thickness" rmax="BP_radius" zhalf="Endcap_zmax/2.0"/>
3   <position x="0" y="0" z="Endcap_zmax/2.0" />
4   <rotation x="0.0" y="CrossingAngle/2.0" z="0.0" />
5   <layer id="1" inner_r="Barrel_r1"
6     outer_r="Barrel_r1 + 0.02*cm" inner_z="Barrel_zmax + 0.1*cm">
7     <slice material = "G10" thickness ="0.5*cm"/>
8   </layer>
9   <layer id="2" inner_r="Barrel_r2"
10  outer_r="Barrel_r2 + 0.02*cm" inner_z="Barrel_zmax + 0.1*cm">
11    <slice material = "G10" thickness ="0.5*cm"/>
12  </layer>
13  ....
14 </detector>

```

The variable names used in the XML snippet are evaluated when interpreted. Unless the attributes are accessed as strings, the client never sees the strings, but only the evaluated numbers. The anatomy of the C++ code snippets to interpret such a data section looks very similar:

```

1 static void some_xml_handler(xml_h e) {
2   xml_det_t x_det (e);
3   xml_comp_t x_tube = x_det.tubs();
4   xml_dim_t pos = x_det.position();
5   xml_dim_t rot = x_det.rotation();
6   string name = x_det.nameStr();
7
8   for(xml_coll_t i(x_det,_U(layer)); i; ++i) {
9     xml_comp_t x_layer = i;
10    double zmin = x_layer.inner_z();
11    double rmin = x_layer.inner_r();
12    double rmax = x_layer.outer_r();
13    double layerWidth = 0;
14
15    for(xml_coll_t j(x_layer,_U(slice)); j; ++j) {
16      double thickness = xml_comp_t(j).thickness();
17      layerWidth += thickness;
18    }
19  }
20 }

```

In the above code snippet an XML (sub-)tree is passed to the executing function as a handle to an XML element (`xml_h`). Such handles may seamlessly be assigned to any supporting helper class inheriting from the class `XML::Element`, which encapsulates the functionality required to interpret the XML structures. Effectively the various XML attributes and child nodes are accessed using functions with the same name from a convenience handle. In lines 3-5 child nodes are extracted, lines 10-12,16 access element attributes. Element collections with the same tag names `layer` and `slice` are exposed to the client code using an iteration mechanism. The convenience handles actually implement these functions to ease life. There is no magic - newly created attributes with new names obviously cannot be accessed with convenience mechanism. Hence, either you know what you are doing and you create your own convenience handlers or you restrict yourself a bit in the creativity of defining new attribute names.

There exist several utility classes to extract data from predefined XML tags:

- Any XML element is described by an XML handle `XML::Handle_t` (`xml_t`). Handles are the basic structure for the support of higher level interfaces described above. The assignment of a handle to any of the interfaces below is possible.
- The class `XML::Element` (`xml_elt_t`) supports in a simple way the navigation through the hierarchy of the XML tree accessing child nodes and attributes. Attributes at this level are named entities and the tag name must be supplied.
- The class `XML::Dimension` with the type definition `xml_dim_t`, supports numerous access functions named identical to the XML attribute names. Such helper classes simplify the tedious string handling required by the
- The class `XML::Component` (`xml_comp_t`) and the class `XML::Detector` (`xml_det_t`) resolving other issues useful to construct detectors.
- Sequences of XML elements with an identical tag name may be handled as iterations as shown in the Figure above using the class `XML::Collection_t`.
- Convenience classes, which allow easy access to element attributes may easily be constructed using the methods of the `XML::Element` class. This allows to construct very flexible thou non-intrusive extensions to DD4hep. Hence there is a priori no need to modify these helpers for the benefit of only one single client. In the presence of multiple requests such extensions may though be adopted.

It is clearly the responsibility of the client to only request attributes from an XML element, which exist. If an attribute, a child node etc. is not found within the element an exception is thrown.

The basic interface of the `XML::Element` class allows to access tags and child nodes not exposed by the convenience wrappers:

```

1  /// Access the tag name of this DOM element
2  std::string tag() const;
3  /// Access the tag name of this DOM element
4  const XmlChar* tagName() const;
5
6  /// Check for the existence of a named attribute
7  bool hasAttr(const XmlChar* name) const;
8  /// Retrieve a collection of all attributes of this DOM element
9  std::vector<Attribute> attributes() const;
10 /// Access single attribute by it's name
11 Attribute getAttr(const XmlChar* name) const;
12 /// Access attribute with implicit return type conversion
13 template <class T> T attr(const XmlChar* tag) const;
14 /// Access attribute name (throws exception if not present)
15 const XmlChar* attr_name(const Attribute attr) const;
16 /// Access attribute value by the attribute (throws exception if not present)
17 const XmlChar* attr_value(const Attribute attr) const;
18
19 /// Check the existence of a child with a given tag name
20 bool hasChild(const XmlChar* tag) const;
21 /// Access child by tag name. Thow an exception if required in case the child is not present
22 Handle_t child(const Strng_t& tag, bool except = true) const;
23 /// Add a new child to the DOM node
24 Handle_t addChild(const XmlChar* tag) const;
25 /// Check if a child with the required tag exists - if not create it and add it to the current node
26 Handle_t setChild(const XmlChar* tag) const;

```

2.5 The Detector Description Data Hub: LCDD

As shown in Figure 2, any access to the detector description data is done using a standardized interface called *LCDD*. During the configuration phase of the detector the interface is used to populate the internal data structures. Data structures present in the memory layout of the detector description may be retrieved by clients at any time using the LCDD interface class. This includes of course, the access during the actual detector construction. The following code listing shows the accessor method to retrieve detector description entities from the interface. Not shown are access methods for groups of these entities and the methods to add objects:

```
1 struct LCDD {
2
3   ///+++ Shortcuts to access often used quantities
4
5   /// Return handle to material describing air
6   virtual Material air() const = 0;
7   /// Return handle to material describing vacuum
8   virtual Material vacuum() const = 0;
9   /// Return handle to "invisible" visualization attributes
10  virtual VisAttr invisible() const = 0;
11
12  ///+++ Access to the top level detector elements and the corresponding volumes
13
14  /// Return reference to the top-most (world) detector element
15  virtual DetElement world() const = 0;
16  /// Return reference to detector element with all tracker devices.
17  virtual DetElement trackers() const = 0;
18
19  /// Return handle to the world volume containing everything
20  virtual Volume worldVolume() const = 0;
21  /// Return handle to the volume containing the tracking devices
22  virtual Volume trackingVolume() const = 0;
23
24  ///+++ Access to geometry and detector description objects
25
26  /// Retrieve a constant by it's name from the detector description
27  virtual Constant constant(const std::string& name) const = 0;
28  /// Retrieve a material by it's name from the detector description
29  virtual Material material(const std::string& name) const = 0;
30  /// Retrieve a field component by it's name from the detector description
31  virtual DetElement detector(const std::string& name) const = 0;
32  /// Retrieve a sensitive detector by it's name from the detector description
33  virtual SensitiveDetector sensitiveDetector(const std::string& name) const = 0;
34  /// Retrieve a readout object by it's name from the detector description
35  virtual Readout readout(const std::string& name) const = 0;
36  /// Retrieve a id descriptor by it's name from the detector description
37  virtual IDDescriptor idSpecification(const std::string& name) const = 0;
38  /// Retrieve a subdetector element by it's name from the detector description
39  virtual CartesianFieldfield(const std::string& name) const = 0;
40
41  ///+++ Access to visualisation attributes and Geant4 processing hints
42
43  /// Retrieve a visualization attribute by it's name from the detector description
44  virtual VisAttr visAttributes(const std::string& name) const = 0;
45
46  /// Retrieve a region object by it's name from the detector description
47  virtual Region region(const std::string& name) const = 0;
48  /// Retrieve a limitset by it's name from the detector description
```

```

49 virtual LimitSet      limitSet(const std::string& name)      const = 0;
50 /// Retrieve an alignment entry by it's name from the detector description
51 virtual AlignmentEntry alignment(const std::string& path)      const = 0;
52 ...
53
54 ///+++ Extension mechanism:
55
56 /// Extend the sensitive detector element with an arbitrary structure accessible by the type
57 template <typename IFACE, typename CONCRETE> IFACE* addExtension(CONCRETE* c);
58 /// Access extension element by the type
59 template <class T> T* extension() const;
60 };

```

As shown in the above listing, the *LCDD* interface is the main access point to access a whole set

- often used predefined values such as the material "air" or "vacuum" (line 5-10).
- the top level objects "world", "trackers" and the corresponding volumes (line 14-22).
- items in the constants table containing named definitions also used during the interpretation of the XML content after parsing (line 27)
- named items in the the material table (line 29)
- named subdetectors after construction and the corresponding (line 31)
- named sensitive detectors with their (line 33)
- named readout structure definition using a (line 35)
- named readout identifier descriptions (line 37)
- named descriptors of electric and/or magnetic fields (line 39).

Additional support for specialized applications is provided by the interface:

- Geant4: named region settings (line 47)
- Geant4: named limits settings (line 49)
- Visualization: named visualization attributes (line 44)
- Alignment: named alignment entries to correct displaced volumes (line 51)
- User defined extensions (line 56-59) are supported with the extension mechanism described in section 2.3.

All the values are populated either directly from XML or from **detector – constructors** (see section 1.2.2). The interface also allows to load XML configuration files of any kind provided an appropriate interpretation plugin is present. In the next section we describe the functionality of the "lcdd" plugin used to interpret the compact detector description. This mechanism can easily be extended using ROOT plugins, where the plugin name must correspond to the XML root element of the document to be interpreted.

2.6 Detector Description Persistency in XML

As explained in a previous section, the mechanism involved in the data loading allow an application to be fairly independent of the technology used to populate the transient detector representation. However, if one wants to use a given technology, she/he has to get/provide the corresponding conversion mechanism. Though DD4hep also supports the population of the detector description using python constructs, we want to focus here on the XML based population. The choice of XML was driven mainly by its easiness of use and the number of tools provided for its manipulation and parsing. Moreover, XML data can be easily translated into many other format using tools like XSLT processors. The grammar used for the XML data is pretty simple and straight forward, actually very similar to other geometry description languages based on XML. For example the material description is nearly identical to the material description in GDML [11]. The syntactic structure of the compact XML description was taken from the SiD detector description [9]. The following listing shows the basic layout of any the compact detector description file with its different sections:

```

1 <lccdd>
2   <info>      ...    </info>      Auxiliary detector model information
3   <includes>   ...    </includes>   Section defining GDML files to be included
4   <define>     ...    </define>     Dictionary of constant expressions and variables
5   <materials>  ...    </materials>  Additional material definitions
6   <display>    ...    </display>    Definition of visualization attributes
7   <detectors>  ...    </detectors>  Section with sub-detector definitions
8   <readouts>   ...    </readouts>   Section with readout structure definitions
9   <limits>     ...    </limits>     Definition of limit sets for Geant4
10  <fields>     ...    </fields>     Field definitions
11 </lccdd>

```

The root tag of the XML tree is `lccdd`. This name is fixed. In the following the content of the various sections is discussed. The XML sections are filled with the following information:

- The `< info >` **sub-tree** contains auxiliary information about the detector model:

```

1   <info name="cllc_sid_cdr"
2     title="CLIC Silicon Detector CDR"
3     author="Christian Greife"
4     url="https://twiki.cern.ch/twiki/bin/view/CLIC/CLicSidCdr"
5     status="development"
6     version="$Id: compact.xml 665 2013-07-02 18:49:26Z markus.frank $">
7     <comment>The compact format for the CLIC Silicon Detector used
8       for the conceptual design report</comment>
9   </info>

```

- The `< includes >` **section** allows to include GDML sub-trees containing material descriptions. These files are processed *before* the detector constructors are called:

```

1   <includes>
2     <gdmlFile ref="elements.xml"/>
3     <gdmlFile ref="materials.xml"/>
4     ...
5   </includes>

```

- The `< define >` **section** contains all variable definitions defined by the client to simplify the definition of subdetectors. These name-value pairs are fed to the expression evaluator and MUST evaluate to a number. String constants are not allowed. These variables can be combined to formulas e.g. to automatically re-dimension subdetectors if boundaries are changed:

```

1  <define>
2      <constant name="world_side" value="30000"/>
3      <constant name="world_x" value="world_side"/>
4      <constant name="world_y" value="world_side"/>
5      <constant name="world_z" value="world_side"/>
6      ....
7  </define>

```

- The `< materials >` sub-tree contains additional materials, which are not contained in the default materials tables. The snippet below shows an example to extend the table of known materials. For more details please see section 2.7.

```

1  <materials>
2      <!-- The description of an atomic element or isotope -->
3      <element Z="30" formula="Zn" name="Zn" >
4          <atom type="A" unit="g/mol" value="65.3955" />
5      </element>
6      ...
7      <!-- The description of a new material -->
8      <material name="CarbonFiber_15percent">
9          ...
10     </material>
11     ...
12 </materials>

```

- The **visualization attributes** are defined in the `< display >` section. Clients access visualization settings by name. The possible attributes are shown below and essentially contain the RGB color values, the visibility and the drawing style:

```

1  <display>
2      <vis name="InvisibleNoDaughters" showDaughters="false" visible="false"/>
3      <vis name="SiVertexBarrelModuleVis"
4          alpha="1.0" r="1" g="1" b="0.6"
5          drawingStyle="solid"
6          showDaughters="true"
7          visible="true"/>
8      ...
9  </display>

```

- **Limisets** contain parameters passed to Geant4:

```

1  <limits>
2      <limitset name="cal_limits">
3          <limit name="step_length_max" particles="*" value="5.0" unit="mm" />
4      </limitset>
5  </limits>

```

- The `< detectors >` section contains subtrees of the type `< detector >` which contain all parameters used by the *detectorconstructors* to actually expand the geometrical structure. Each subdetector has a name and a type, where the type is used to call the proper constructor plugin. If the subdetector element is sensitive, a forward reference to the corresponding readout structure is mandatory. The remaining parameters are user defined:

```

1      <detectors>
2          <detector id="4" name="SiTrackerEndcap" type="SiTrackerEndcap" readout="SiTrackerEndcapHits">
3              <comment>Outer Tracker Endcaps</comment>
4              <module name="Module1" vis="SiTrackerEndcapModuleVis">
5                  <trd x1="36.112" x2="46.635" z="100.114/2" />
6                  <module_component thickness="0.00052*cm" material="Copper" />
7                  <module_component thickness="0.03*cm" material="Silicon" sensitive="true" />
8                  ...
9              </module>
10             ...
11             <layer id="1">
12                 <ring r="256.716" zstart="787.105+1.75" nmodules="24" dz="1.75" module="Module1"/>
13                 <ring r="353.991" zstart="778.776+1.75" nmodules="32" dz="1.75" module="Module1"/>
14                 <ring r="449.180" zstart="770.544+1.75" nmodules="40" dz="1.75" module="Module1"/>
15             </layer>
16             ...
17         </detector>
18     </detectors>

```

- **The < readouts > section** defined the encoding of sensitive volumes to so-called cell-ids, which are in DD4hep 64-bit integer numbers. The encoding is subdetector dependent with one exception: to uniquely identity each subdetector, the width of the system field must be the same. The usage of these data is discussed in section ??.

```

1      <readouts>
2          <readout name="SiTrackerEndcapHits">
3              <id>system:8,barrel:3,layer:4,module:14,sensor:2,side:32:-2,strip:20</id>
4          </readout>
5          ...
6      </readouts>

```

- **Electromagnetic fields** are described in the < fields > section. There may be several fields present. In DD4hep the resulting field vectors may be both electric and magnetic. The strength of the overall field is calculated as the superposition of the individual components:

```

1      <fields>
2          <field name="GlobalSolenoid" type="solenoid">
3              inner_field="5.0*tesla"
4              outer_field="-1.5*tesla"
5              zmax="SolenoidCoilOuterZ"
6              outer_radius="SolenoidalFieldRadius">
7          </field>
8          ...
9      </fields>

```

2.7 Material Description

Materials are needed by logical volumes. They are defined as isotopes, elements or mixtures. Elements can optionally be composed of isotopes. Composition is always done by specifying the fraction of the mass. Mixtures can be composed of elements or other mixtures. For a mixture the user can specify composition either by number of atoms or by fraction of mass. The materials sub-tree in section 2.6 shows the representation of an element, a simple material and a composite material in the XML format identical to GDML [11]. The snippet below shows how to define new material instances:

```

1 <materials>
2   ...
3   <!-- (1) The description of an atomic element or isotope -->
4   <element Z="30" formula="Zn" name="Zn" >
5     <atom type="A" unit="g/mol" value="65.3955" />
6   </element>
7   <!-- (2) A composite material -->
8   <material name="Kapton">
9     <D value="1.43" unit="g/cm3" />
10    <composite n="22" ref="C"/>
11    <composite n="10" ref="H" />
12    <composite n="2" ref="N" />
13    <composite n="5" ref="O" />
14  </material>
15  <!-- (3) A material mixture -->
16  <material name="PyrexGlass">
17    <D type="density" value="2.23" unit="g/cm3"/>
18    <fraction n="0.806" ref="SiliconOxide"/>
19    <fraction n="0.130" ref="BoronOxide"/>
20    <fraction n="0.040" ref="SodiumOxide"/>
21    <fraction n="0.023" ref="AluminumOxide"/>
22  </material>
23  ...
24 </materials>

```

The `< materials >` sub-tree contains additional materials, which are not contained in the default materials tables. The snippet above shows different kinds of materials:

- (1) Atomic elements as they are in the periodic table. The number of elements is finite. It is unlikely any client will have to extend the known elements.
- (2) Composite materials, which consists of one or several elements forming a molecule. These materials have a certain density under normal conditions described in the child element `D`. For each `composite` the attribute `ref` denotes the element type by name, the attribute `n` denotes the atomic multiplicity. Typically each of the elements in (1) also forms such a material representing objects which consist of pure material like e.g. iron magnet yokes or copper wires.
- (3) Last there are mixtures of composite materials to describe for example alloys, solutions or other mixtures of solid materials. This is the type of material used to actually create mechanical structures forming the assembly of an experiment. Depending on the manufacturing these materials have a certain density (`D`) and are composed of numerous molecules contributing to the resulting material with a given `fraction`. The sum of all fractions (attribute `n`) is 1.0.

"Real" materials i.e. those you can actually touch are described in TGeo by the class `TGeoMedium`². Materials are not constructed by any client. Materials and elements are either already present in the corresponding tables of the ROOT geometry package or they are added during the interpretation of the XML input. Clients access the description of material using the LCDD interface.

²Typical beginner's mistake: Do not mix up the two classes `TGeoMaterial` and `TGeoMedium`! The material to define volumes is of type `TGeoMedium`, which also includes the description of the material's finish.

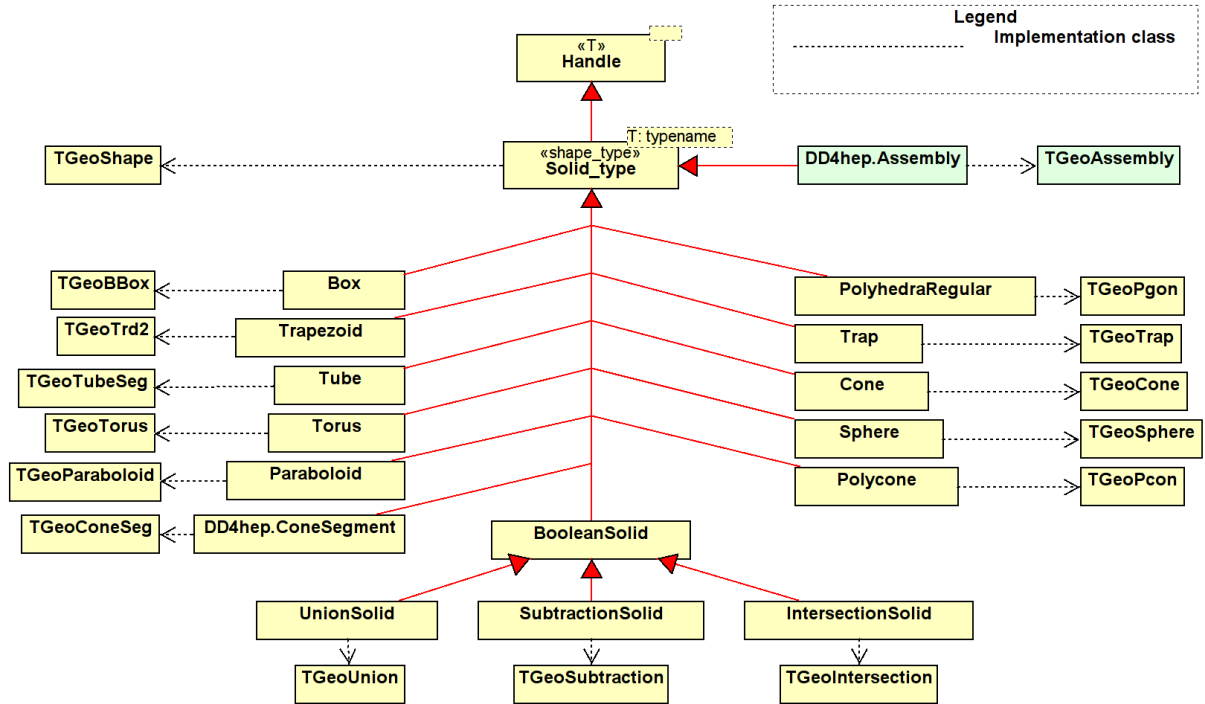

Figure 5: Extensions may be attached to common Detector Elements which extend the functionality of the common DetElement class and support e.g. caching of precomputed values.

2.8 Shapes

Shapes are abstract objects with a bounding surface and fixed dimensions. There are primitive, atomic shapes and complex boolean shapes as shown in Figure 5. TGeo and similarly Geant4 offer a whole palette of primitive shapes, which can be used to construct more complex shapes:

- Box shape represented by the TGeoBBox class. To create a new box object call one of the following constructors:

```

1  /// Constructor to be used when creating an anonymous new box object
2  Box(double x, double y, double z);
3  /// Constructor to be used when creating an anonymous new box object
4  template<typename X, typename Y, typename Z> Box(const X& x, const Y& y, const Z& z);

```

- Sphere shape represented by the TGeoSphere class. To create a new sphere object call one of the following constructors:

```

1

```

- Cone shape represented by the TGeoCone class. To create a new cone object call one of the following constructors:

```

1  /// Constructor to create a new anonymous object with attribute initialization
2  Cone(double z, double rmin1, double rmax1, double rmin2, double rmax2);
3  template<typename Z, typename RMIN1, typename RMAX1, typename RMIN2, typename RMAX2>
4  Cone(const Z& z, const RMIN1& rmin1, const RMAX1& rmax1, const RMIN2& rmin2, const RMAX2& rmax2);

```

- Cone segment shape represented by the TGeoConeSeg class. To create a new cone segment object call one of the following constructors:

```

1  /// Constructor to create a new ConeSegment
2  ConeSegment(double dz, double rmin1, double rmax1, double rmin2, double rmax2,
3              double phi1=0.0, double phi2=2.0*M_PI);

```

- Polycone shape represented by the `TGeoPcon` class. To create a new polycone object call one of the following constructors:

```

1  /// Constructor to create a new polycone object
2  Polycone(double start, double delta);
3  followed by a call to:
4  void addZPlanes(const std::vector<double>& rmin,
5                 const std::vector<double>& rmax,
6                 const std::vector<double>& z);
7  /// Constructor to create a new polycone object. Add at the same time all Z planes
8  Polycone(double start, double delta,
9            const std::vector<double>& rmin,
10           const std::vector<double>& rmax,
11           const std::vector<double>& z);

```

- Tube segment shape represented by the `TGeoTubeSeg` class. To create a new tube segment object call one of the following constructors:

```

1  Tube(double rmin, double rmax, double z, double deltaPhi=2*M_PI)
2  Tube(double rmin, double rmax, double z, double startPhi, double deltaPhi)
3
4  template<typename RMIN, typename RMAX, typename Z, typename DELTAPHI>
5  Tube(const RMIN& rmin, const RMAX& rmax, const Z& z, const DELTAPHI& deltaPhi)
6
7  template<typename RMIN, typename RMAX, typename Z, typename STARTPHI, typename DELTAPHI>
8  Tube(const std::string& name, const RMIN& rmin, const RMAX& rmax, const Z& z,
9       const STARTPHI& startPhi, const DELTAPHI& deltaPhi)

```

- Trapezoid shape represented by the `TGeoTrd` class. To create a new trapezoid object call one of the following constructors:

```

1  /// Constructor to create a new anonymous object with attribute initialization
2  Trapezoid(double x1, double x2, double y1, double y2, double z);

```

- Trap shape represented by the `TGeoTrap` class. To create a new trap object call one of the following constructors:

```

1  /// Constructor to create a new anonymous object with attribute initialization
2  Trap(double z,double theta,double phi,
3       double y1,double x1,double x2,double alpha1,
4       double y2,double x3,double x4,double alpha2);
5  /// Constructor to create a new anonymous object for right angular wedge from STEP (Se G4 manual for details)
6  Trap( double pz, double py, double px, double pLTX);

```

- Torus shape represented by the `TGeoTorus` class. To create a new torus object call one of the following constructors:

```

1  /// Constructor to create a new anonymous object with attribute initialization
2  Torus(double r, double rmin, double rmax, double phi=M_PI, double delta_phi=2.*M_PI);

```

- Paraboloid shape represented by the `TGeoParaboloid` class. To create a new paraboloid object call one of the following constructors:

```

1  /// Constructor to create a new anonymous object with attribute initialization
2  Paraboloid(double r_low, double r_high, double delta_z);

```

- Regular Polyhedron shape represented by the `TGeoPgon` class. To create a new polyhedron object call one of the following constructors:

```
1  /// Constructor to create a new object. Phi(start)=0, deltaPhi=2PI, Z-planes at +-zlen/2
2  PolyhedraRegular(int nsides, double rmin, double rmax, double zlen);
3  /// Constructor to create a new object. Phi(start)=0, deltaPhi=2PI, Z-planes at zplanes[0],[1]
4  PolyhedraRegular(int nsides, double rmin, double rmax, double zplanes[2]);
5  /// Constructor to create a new object with phi_start, deltaPhi=2PI, Z-planes at +-zlen/2
6  PolyhedraRegular(int nsides, double phi_start, double rmin, double rmax, double zlen);
```

Besides the primitive shapes three types of boolean shapes (described in TGeo by the `TGeoCompositeShape` class) are supported:

- `UnionSolid` objects representing the union,
- `IntersectionSolid` objects representing the intersection,
- `SubtractionSolid` objects representing the subtraction,

of two other primitive or complex shapes. To build a boolean shape, the second shape is transformed in 3-dimensional space before the boolean operation is applied. The 3D transformations are described by objects from the `ROOT::Math` library and are supplied at construction time. Such a transformation as shown in the code snippet below may be

- The identity transformation. Then no transformation object needs to be provided (see line 2).
- A translation only described by a `Position` object (see line 4)
- A 3-fold rotation first around the Z-axis, then around the Y-axis and finally around the X-axis. For transformation operations of this kind a `RotationZYX` object must be supplied (see line 6).
- A generic 3D rotation matrix should be applied to the second shape. Then a `Rotation3D` object must be supplied (see line 8).
- Finally a generic 3D transformation (translation+rotation) may be applied using a `Transform3D` object (see line 10).

All three boolean shapes have constructors as shown here for the `UnionSolid`:

```
1  /// Constructor to create a new object. Position is identity, Rotation is identity-rotation!
2  UnionSolid(const Solid& shape1, const Solid& shape2);
3  /// Constructor to create a new object. Placement by position, Rotation is identity-rotation!
4  UnionSolid(const Solid& shape1, const Solid& shape2, const Position& pos);
5  /// Constructor to create a new object. Placement by a RotationZYX within the mother
6  UnionSolid(const Solid& shape1, const Solid& shape2, const RotationZYX& rot);
7  /// Constructor to create a new object. Placement by a generic rotation within the mother
8  UnionSolid(const Solid& shape1, const Solid& shape2, const Rotation3D& rot);
9  /// Constructor to create a new object. Placement by a generic transformation within the mother
10 UnionSolid(const Solid& shape1, const Solid& shape2, const Transform3D& pos);
```

2.9 Volumes and Placements

The detector geometry is described by a hierarchy of volumes and their corresponding placements. Both, the TGeo package and Geant4 [8] are following effectively the same ideas ensuring an easy conversion from TGeo to Geant4 objects for the simulation application. A volume is an unplaced solid described in terms of a primitive shape or a boolean operation of solids, a material and a number of placed sub-volumes (placed volumes) inside. The class diagram showing the relationships between volumes and placements, solids and materials is shown in Figure 2. It is worth noting, that any volume has children, but no parent or "mother" volume. This is a direct consequence of the requirement to re-use volumes and place the same volume arbitrarily often. Only the act of placing a volume defines the relationship to the next level parent volume. The resulting geometry tree is very effective, simple and convenient to describe the detector geometry hierarchy starting from the top level volume representing e.g. the experiment cavern down to the very detail of the detector e.g. the small screw in the calorimeter. The top level volume is the very only volume without a placement. All geometry calculations, computations are always performed within the local coordinate system of the volume. The following example code shows how to create a volume which consists of a given material and with a shape. The created volume is then placed inside the mother-volume using the local coordinate system of the mother volume:

```

1 Volume      mother = ....ampercent
2
3 Material    mat      (lcdd.material("Iron"));
4 Tube        tub      (rmin, rmax, zhalf);
5 Volume      vol      (name, tub, mat);
6 Transform3D tr      (RotationZYX(rotz,roty,rotx),Position(x,y,z));
7 PlacedVolume phv = mother.placeVolume(vol,tr);

```

The volume has the shape of a tube and consists of iron. Before being placed, the daughter volume is transformed within the mother coordinate system according to the requested transformation. The example also illustrates how to access *Material* objects from the *LCDD* interface.

The *Volume* class provides several possibilities to declare the required space transformation necessary to place a daughter volume within the mother:

- to place a daughter volume unrotated at the origin of the mother, the transformation is the identity. Use the following call to place the daughter:
`PlacedVolume placeVolume(const Volume& vol) const;`
- If the positioning is described by a simple translation, use:
`PlacedVolume placeVolume(const Volume& vol, const Position& pos) coampercentnst;`
- In case the daughter should be rotated first around the Z-axis, then around the Y-axis and finally around the X-axis place the daughter using this call:
`PlacedVolume placeVolume(const Volume& vol, const RotationZYX& rot) const;`
- If the full 3-dimensional rotation matrix is known use:
`PlacedVolume placeVolume(const Volume& vol, const Rotation3D& rot) const;`
- for an entirely unconstrained placement place the daughter providing a *Transform3D* object:
`PlacedVolume placeVolume(const Volume& volume, const Transform3D& tr) const;`

For more details of the *Volume* and the *PlacedVolume* classes please see the header file .

One volume like construct is special: the assembly constructs. Assemblies are volumes without shapes. The "assembly" shape does not own a own surface by itself, but rather defines it's surface and bounding box from the contained children. In this corner also the implementation concepts between TGeo and Geant4 diverge. Whereas TGeo handles assemblies very similar to real volumes, in Geant4 assemblies are purely artificial and disappear at the very moment volumes are placed.

2.10 Detector Elements

Detector elements (class `DetElement`) are entities which represent subdetectors or sizable parts of a subdetector. As shown in Figure 6, a `DetElement` instance has the means to provide to clients information about

- generic properties like the detector type or the path within the `DetElements` hierarchy:

```
1    /// Access detector type (structure, tracker, calorimeter, etc.).
2    std::string type() const;
3    /// Path of the detector element (not necessarily identical to placement path!)
4    std::string path() const;
```

- the detector hierarchy by exposing its children. The hierarchy may be accessed with the following API:

```
1    /// Add new child to the detector structure
2    DetElement& add(DetElement sub_element);
3    /// Access to the list of children
4    const Children& children() const;
5    /// Access to individual children by name
6    DetElement child(const std::string& name) const;
7    /// Access to the detector elements's parent
8    DetElement parent() const;
```

- its placement within the overall experiment if it represents an entire subdetector or its placement with respect to its parent if the `DetElement` represents a part of a subdetector. The placement path is the fully qualified path of placed volumes from the top level volume to the placed detector element and may serve as a shortcut for the alignment implementation:

```
1    /// Access to the full path to the placed object
2    std::string placementPath() const;
3    /// Access to the physical volume of this detector element
4    PlacedVolume placement() const;
5    /// Access to the logical volume of the daughter placement
6    Volume volume() const;
```

- information about the environmental conditions etc. (`conditions`):

```
1    /// Access to the conditions information
2    Conditions conditions() const;
```

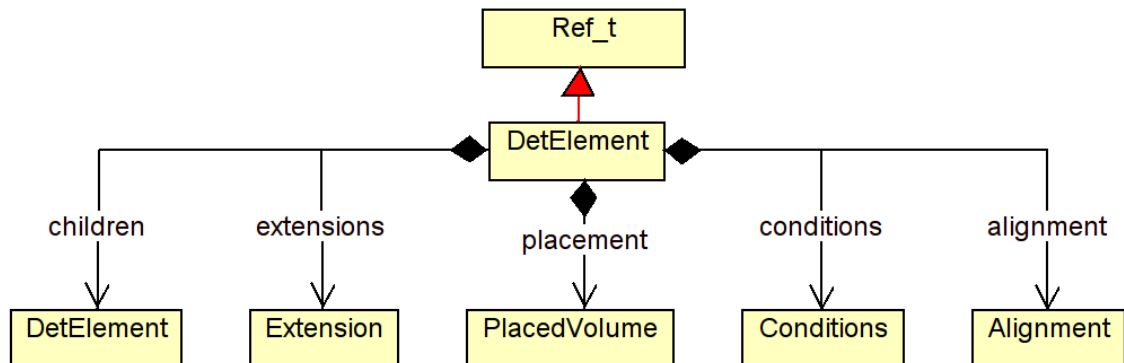

Figure 6: The basic layout of the `DetElement` class aggregating all data entities necessary to process data.

- alignment information:

```
1    /// Access to the alignment information
2    Alignment alignment() const;
```

- convenience information such as cached transformations to/from the top level volume, to/from the parent DetElement and to/from another DetElement in the hierarchy above:

```
1    /// Transformation from local coordinates of the placed volume to the world system
2    bool localToWorld(const Position& local, Position& global) const;
3    /// Transformation from world coordinates of the local placed volume coordinates
4    bool worldToLocal(const Position& global, Position& local) const;
5
6    /// Transformation from local coordinates of the placed volume to the parent system
7    bool localToParent(const Position& local, Position& parent) const;
8    /// Transformation from world coordinates of the local placed volume coordinates
9    bool parentToLocal(const Position& parent, Position& local) const;
10
11   /// Transformation from local coordinates of the placed volume to arbitrary parent system set as reference
12   bool localToReference(const Position& local, Position& reference) const;
13   /// Transformation from world coordinates of the local placed volume coordinates
14   bool referenceToLocal(const Position& reference, Position& local) const;
15
16   /// Set detector element for reference transformations.
17   /// Will delete existing reference transformation.
18   DetElement& setReference(DetElement reference);
```

- User extension information as described in section 2.3:

```
1    /// Extend the detector element with an arbitrary structure accessible by the type
2    template <typename IFACE, typename CONCRETE> IFACE* addExtension(CONCRETE* c);
3    /// Access extension element by the type
4    template <class T> T* extension() const;
```

2.11 Sensitive Detectors

Though the concept of sensitive detectors comes from Geant4 and simulation activities, in DD4hep the sensitive detectors are the client interface to access the readout description (class `Readout`) with its segmentation of sensitive elements (class `Segmentation`) and the description of hit decoders (class `IDDescriptors`). As shown in Figure 8, these object instances are required when reconstructing data from particle collisions.

Besides the access to data necessary for reconstruction the sensitive detector also hosts Region setting (class `Region` and sets of cut limits (class `LimitSets`) used configure the Geant4 simulation toolkit. The following code snippet shows the accessors of the `SensitiveDetector` class to obtain the corresponding information ³:

```

1  struct SensitiveDetector: public Ref_t {
2      /// Access the hits collection name
3      const std::string& hitsCollection() const;
4      /// Access readout structure of the sensitive detector
5      Readout readout() const;
6      /// Access to the region setting of the sensitive detector (not mandatory)
7      Region region() const;
8      /// Access to the limit set of the sensitive detector (not mandatory).
9      LimitSet limits() const;
10
11     /// Extend the sensitive detector element with an arbitrary structure accessible by the type
12     template <typename IFACE, typename CONCRETE> IFACE* addExtension(CONCRETE* c);
13     /// Access extension element by the type
14     template <class T> T* extension() const;
15 };

```

Figure 7: The structure of DD4hep sensitive detectors.

Sensitive detector objects are automatically creating using the information of the `< readout >` section of the XML file if a subdetector is sensitive and references a valid readout entry. In the detector constructor (or any time later) clients may add additional information to a sensitive detector object using an extension mechanism similar to the extension mechanism for detector elements mentioned earlier.

Volumes may be shared and reused in several placements. In the parallel hierarchy of detector elements as shown in Figure 3, the detector elements may reference unambiguously the volumes of their respective placements, but not the reverse. However, the sensitive detector setup is a single instance per

³The methods to set the data are not shown here.

subdetector. Hence it may be referenced by all sensitive Volumes of one subdetector. In the following chapters the access to the readout structure is described.

2.12 Description of the Readout Structure

The **Readout** class describes the detailed structure of a sensitive volume. The for example may be the layout of strips or pixels in a silicon detector i.e. the description of entities which would not be modeled using individual volumes and placements though this would theoretically be feasible. Each sensitive element is segmented according to the **Segmentation** object and hits resulting from energy depositions in the sensitive volume are encoded using the **IDDescriptor** object.

Figure 8: The basic components to describe the **Readout** structure of a subdetector.

2.12.1 CellID Descriptors

IDDescriptors define the encoding of sensitive volumes to uniquely identify the location of the detector response. The encoding defines a bit-field with the length of 64 bits. The first field is mandatory called **system** and identifies the subdetector. All other fields define the other volumes in the hierarchy. The high bits are not necessarily mapped to small daughter volumes, but may simply identify a logical segmentation such as the **stripnumber** within a wafer of a vertex detector as shown in the following XML snippet:

```

1 <readouts>
2   <readout name="SiVertexEndcapHits">
3     <id>system:8,barrel:3,layer:4,module:14,sensor:2,side:32:-2,strip:24</id>
4   </readout>
5 </readouts>

```

These identifiers are the data input to **segmentationclasses** 2.12.2, which define a user friendly API to en/decode the detector response.

2.12.2 Segmentations

Segmentations define the user API to the low level interpretation of the energy deposits in a subdetector. For technical reasons and partial religious reasons are the segmentation implementation not part of the DD4hep toolkit, but an independent package call **DDSegmentation** [12]. Though the usage is an integral part of DD4hep.

2.13 Detector Constructors

The creation of appropriate detector constructors is the main work of a client defining his own detector. The detector constructor is a fragment of code in the form of a routine, which return a handle to the created subdetector `DetElement` object.

Knowing that detector constructors are the main work items of clients significant effort was put in place to ease and simplify this procedure as much as possible in order to obtain readable, still compact code hopefully easy to maintain. The interfaces to all objects, XML accessors, shapes, volumes etc. which were discussed above were optimized to support this intention.

To illustrate the anatomy of such a constructor the following code originating from an existing SiD detector concept will be analyzed. The example starts with the XML input data. Further down this section the code is shown with a detailed description of every relevant line. The object to be build is a subdetector representing a layered calorimeter, where each layer consists of a number of slices as shown in the XML snippet. These layers are then repeated a number of times.

The XML snippet describing the subdetector properties:

```

1 <detector id="13" name="LumiCal" reflect="true" type="CylindricalEndcapCalorimeter"
2   readout="LumiCalHits" vis="LumiCalVis" calorimeterType="LUMI">
3   <comment>Luminosity Calorimeter</comment>
4   <dimensions inner_r = "LumiCal_rmin" inner_z = "LumiCal_zmin" outer_r = "LumiCal_rmax" />
5   <layer repeat="20" >
6     <slice material = "TungstenDens24" thickness = "0.271*cm" />
7     <slice material = "Silicon" thickness = "0.032*cm" sensitive = "yes" />
8     <slice material = "Copper" thickness = "0.005*cm" />
9     <slice material = "Kapton" thickness = "0.030*cm" />
10    <slice material = "Air" thickness = "0.033*cm" />
11  </layer>
12  <layer repeat="15" >
13    <slice material = "TungstenDens24" thickness = "0.543*cm" />
14    <slice material = "Silicon" thickness = "0.032*cm" sensitive = "yes" />
15    <slice material = "Copper" thickness = "0.005*cm" />
16    <slice material = "Kapton" thickness = "0.030*cm" />
17    <slice material = "Air" thickness = "0.033*cm" />
18  </layer>
19 </detector>

```

The C++ code snippet interpreting the XML data and expanding the geometry:

```

1 #include "DD4hep/DetFactoryHelper.h"
2 #include "XML/Layering.h"
3
4 using namespace std;
5 using namespace DD4hep;
6 using namespace DD4hep::Geometry;
7
8 static Ref_t create_detector(LCDD& lcdd, xml_h e, SensitiveDetector sens) {
9   xml_det_t x_det = e;
10  string det_name = x_det.nameStr();
11  bool reflect = x_det.reflect();
12  xml_dim_t dim = x_det.dimensions();
13  double zmin = dim.inner_z();
14  double rmin = dim.inner_r();
15  double rmax = dim.outer_r();
16  double totWidth = Layering(x_det).totalThickness();
17  double z = zmin;
18  Material air = lcdd.air();
19  Tube envelope (rmin,rmax,totWidth,0,2*M_PI);

```

```

20 Volume      envelopeVol(det_name+"_envelope",envelope,air);
21 int          layer_num = 1;
22 PlacedVolume pv;
23
24 // Set attributes of slice
25 for(xml_coll_t c(x_det,_U(layer)); c; ++c) {
26     xml_comp_t x_layer = c;
27     double layerWidth = 0;
28     for(xml_coll_t l(x_layer,_U(slice)); l; ++l)
29         layerWidth += xml_comp_t(l).thickness();
30
31     for(int i=0, m=0, repeat=x_layer.repeat(); i<repeat; ++i, m=0) {
32         double      zlayer = z;
33         string      layer_name = det_name + _toString(layer_num,"_layer%d");
34         Volume      layer_vol(layer_name,Tube(rmin,rmax,layerWidth),air);
35
36         for(xml_coll_t l(x_layer,_U(slice)); l; ++l, ++m) {
37             xml_comp_t x_slice = l;
38             double      w = x_slice.thickness();
39             string      slice_name = layer_name + _toString(m+1,"slice%d");
40             Material    slice_mat = lcdd.material(x_slice.materialStr());
41             Volume      slice_vol (slice_name,Tube(rmin,rmax,w),slice_mat);
42
43             if ( x_slice.isSensitive() ) {
44                 sens.setType("calorimeter");
45                 slice_vol.setSensitiveDetector(sens);
46             }
47             slice_vol.setAttributes(lcdd,x_slice.regionStr(),x_slice.limitsStr(),x_slice.visStr());
48             pv = layer_vol.placeVolume(slice_vol,Position(0,0,z-zlayer-layerWidth/2+w/2));
49             pv.addPhysVolID("slice",m+1);
50             z += w;
51         }
52         layer_vol.setVisAttributes(lcdd,x_layer.visStr());
53         Position layer_pos(0,0,zlayer-zmin-totWidth/2+layerWidth/2);
54         pv = envelopeVol.placeVolume(layer_vol,layer_pos);
55         pv.addPhysVolID("layer",layer_num);
56         ++layer_num;
57     }
58 }
59 // Set attributes of slice
60 envelopeVol.setAttributes(lcdd,x_det.regionStr(),x_det.limitsStr(),x_det.visStr());
61
62 DetElement    sdet(det_name,x_det.id());
63 Volume        motherVol = lcdd.pickMotherVolume(sdet);
64 PlacedVolume phv = motherVol.placeVolume(envelopeVol,Position(0,0,zmin+totWidth/2));
65 phv.addPhysVolID("system",sdet.id())
66     .addPhysVolID("barrel",1);
67 sdet.setPlacement(phv);
68 if ( reflect ) {
69     phv=motherVol.placeVolume(envelopeVol,Transform3D(RotationZ(M_PI),Position(0,0,-zmin-totWidth/2)));
70     phv.addPhysVolID("system",sdet.id())
71         .addPhysVolID("barrel",2);
72 }
73 return sdet;
74 }
75
76 DECLARE_DETELEMENT(CylindricalEndcapCalorimeter,create_detector);

```

Line	
1	The include file <code>DetFactoryHelper.h</code> includes all utilities to extract XML information together with the appropriate type definition.
4-6	Convenience shortcut to save ourself a lot of typing.
8	The entry point to the detector constructor. This routine shall be called by the plugin mechanism.
9	The functionality of the raw XML handle <code>xml.h</code> is rather limited. A simple assignment to a XML detector object gives us all the functionality we need.
10,11	Extracting the sub-detector name and properties from the xml handle.
12-17	Access the <i>dimension</i> child-element from the XML subtree, access the element's attributes and precompute values used later.
18	Retrieve a reference to the "air" material from LCDD.
19-20	Construct the envelope volume shaped as a tube made out of air.
25	Now the detector can be built: We loop over all layers types and over each layer type as often as necessary (attribute: repeat). The XML collection object will return all child elements of <code>x_det</code> with a tag-name "layer".
25	Note the macro <code>_U(layer)</code> : When using Xerces-C as an XML parser, it will expand to the reference to an object containing the unicode value of the string "layer". The full list of predefined tag names can be found in the include file <code>DD4hep/UnicodeValues.h</code> . If a user tag is not part in the precompiled tag list, the corresponding Unicode string may be created with the macro <code>_Unicode(layer)</code> or <code>Unicode("layer")</code> .
26	Convenience assignment to extract attributes of the layer element.
27-29	Compute total layer width.
31	Create <code>repeat</code> number of layers of the same type.
32-34	Create the named envelope volume with a tube shape containing all slices of this layer.
36-51	Create the different layer-slices with a tube shape and the corresponding material as indicated in the XML data.
43-46	If the slice is sensitive i.e. is instrumented and supposed to deliver signals from particle passing, the sensitive detector component of this detector needs to be attached to the slice.
47	Set visualization and geant4 attributes to the slice volume. If the attributes are not present, they will be ignored.
48	Now the created slice volume will be placed inside the mother, the layer envelope at the correct position. This operation results in the creation of a <code>PlacedVolume</code> .
49	It identify uniquely every slice within the layer an identifier (here the number of the created slice) is attached. This identifier must be present in the bitmap defined by the <code>IDDescriptor</code> of this subdetector.
52-55	Same as 47-49, but now the created layer volume is placed in the envelope of the entire sub-detector.
60	Set envelope attributes.
	Construct the main detector element of this subdetector. This will be the unique entry point to access any information of the subdetector.
62	Note: the subdetector may consist of a hierarchy of detector elements. For example each layer could be described by its own <code>DetElement</code> and all layer- <code>DetElement</code> instances being children of the subdetector instance.
63-64	Place the subdetector envelope into its mother (typically the top level (world) volume).
65-66	Add the missing <code>IDDescriptor</code> identifiers to complete the bitmap.
67	Store the placement in the subdetector detector element in order to make it available to later clients of this <code>DetElement</code> .

Line	
68-72	Endcap calorimeters typically are symmetric i.e. an endcap is located on each side of the barrel. To easy such reflections the entire endcap structure can be copied and placed again.
73	All done. Return the created subdetector element to the caller for registration.
76	Very important: Without the registration of the construction function to the framework, the corresponding plugin will not be found. The macro has two arguments: firstly the plugin name which is identical to the detector type in the XML snippet and secondly the function to be called at construction time.

2.14 Tools

2.14.1 Volume Manager

The **VolumeManager** is a tool to seek a lookup table of placements of sensitive volumes and their corresponding unique volume identifier, the **cellID**. The volume manager analyzes - once the geometry is closed - the hierarchical tree and stores the various placements in the hierarchy with respect to their identifiers. In other words the the tree is reused volumes shown e.g. in Figure 3 is degenerated according to the full paths of the various volumes. This use case is very common to reconstruction and analysis applications whenever a given raw-data (aka "hit") element must be related to its geometrical location. Figure 9 shows the design diagram of this component:

Figure 9: Extensions may be attached to common Detector Elements which extend the functionality of the common **DetElement** class and support e.g. caching of precomputed values.

To optimize the access of complex subdetector structures, the volume-identifier map is split and the volumes of each subdetector are stored in a separate map. This optimization however is transparent to clients. The following code extract from the header files lists the main client routines to extract volume information given a known cellID:

```
1  /// Lookup the context, which belongs to a registered physical volume.
2  Context* lookupContext(VolumeID volume_id) const;
3  /// Lookup a physical (placed) volume identified by its 64 bit hit ID
4  PlacedVolume lookupPlacement(VolumeID volume_id) const;
5  /// Lookup a top level subdetector detector element
6  /// according to a contained 64 bit hit ID
7  DetElement lookupDetector(VolumeID volume_id) const;
8  /// Lookup the closest subdetector detector element in the hierarchy
9  /// according to a contained 64 bit hit ID
10 DetElement lookupDetElement(VolumeID volume_id) const;
11 /// Access the transformation of a physical volume to the world coordinate system
12 const TGeoMatrix& worldTransformation(VolumeID volume_id) const;
```
